#### CHAPTER 11

#### RESPONSE RATES AND NONRESPONSE BIAS ANALYSIS

Thomas Krenzke and Leyla Mohadjer, Westat

This chapter provides weighted response rates and a systematic analysis of the potential for nonresponse bias for the household sample and the prison sample of the National Assessment of Adult Literacy (NAAL), separately. The analyses focus on the impact of nonresponse on survey results.

Total survey error has two components: variable error (measured through the calculation of variances) and bias. The variance is the first term in the following equation for total survey error in a survey estimate:

Total survey error = variance + 
$$bias^2$$
. (1)

Bias, the second term in the equation, contains all sources of error other than variable error. A major component of bias is nonresponse, that is, the bias owing to the failure of some selected persons in the sample to respond to the survey. Nonresponse bias can be substantial when two conditions hold: (1) the response rate is relatively low and (2) the difference between the characteristics of respondents and nonrespondents is relatively large.

An estimate for nonresponse bias, assuming that nonresponse is the only source of bias, is expressed in Cochran (1977) as

$$Bias(\overline{y}_R) = (1 - W_R)(\overline{Y}_R - \overline{Y}_N), \tag{2}$$

where  $W_R$  is the response rate and  $\overline{Y}_R$  and  $\overline{Y}_N$  are the mean values of the survey items estimated among the respondents and nonrespondents, respectively. Thus, the estimates from any survey are subject to bias when some selected persons fail to participate in the survey. Because we do not have survey values for nonrespondents, nonresponse bias is not known and can only be estimated.

The following sections provide insights into the effects of nonresponse on the NAAL survey. The unweighted and weighted unit and item response rates are provided for the household study (section 11.1) and the correctional institution sample, known as the prison study (section 11.2). Unweighted response rates are indicators of the success of the data collection effort. Weighted response rates are more appropriate in examining the potential effect of nonresponse on population parameters. Bivariate and

multivariate analyses of the potential for nonresponse bias are provided for both the household study and the prison study.

#### 11.1 HOUSEHOLD LITERACY STUDY

Data from respondents were collected through a screener, a background questionnaire, an assessment, and an oral module. In the nonresponse follow-up strategies, efforts were made to reduce the potential for nonresponse bias by targeting interviewer resources in areas with low response rates. To identify target areas, a multivariate analysis was conducted using a Chi-Squared Automatic Interaction Detector (CHAID) analysis (for more information on CHAID, refer to section 11.1.4.1.2). The resulting classification tree revealed the domains, as defined by combinations of variables, with the most differential response rates, thereby leading to domains with a high potential for nonresponse bias. Overall, the results of the analysis showed acceptable response rates for most of the cells identified by the CHAID program. The analysis, which was conducted for both the screener and the combined background questionnaire/assessment response rates, identified the primary sampling units (PSUs) that included the domains with less than a 70 percent response rate. Field activities and resources were focused on these PSUs in the remaining weeks of the data collection.

After data had been collected and weights produced, a systematic analysis was conducted to examine the impact of bias owing to the remaining nonresponding dwelling units and persons in the household sample. The sections that follow report on the nonresponse bias analysis. Section 11.1.1 gives an overview of the analysis weights. Section 11.1.2 provides unweighted and weighted response rates at the unit level. Section 11.1.3 summarizes response rates at the item level. Section 11.1.4 provides a detailed nonresponse bias analysis for the household study.

## 11.1.1 Analysis Weights

The systematic analysis of nonresponse bias in the household sample, which includes the computation of weighted response rates, used survey weights that were specially created for this analysis. The remainder of this section provides a brief overview of the weighting process for the household study, followed by a brief overview of the nonresponse bias weights used in this analysis.

In the NAAL household study, the nonresponse-adjusted weights were created separately for each of the seven independent samples (NAAL and the six State Assessment of Adult Literacy [SAAL] states). A composite weighting procedure was conducted to combine the NAAL and SAAL samples to improve the survey estimates for the nation and the six SAAL states. More details are provided in section 12.1.

National Center for Education Statistics (NCES) standards for a nonresponse bias analysis require the use of base weights. Because composited screener (dwelling unit-level) and background questionnaire base weights were not created as part of the NAAL household study weighting process, composited base weights were created for this nonresponse bias analysis. An objective of the weight modification process used in the nonresponse bias analysis (as required by the standards) was to minimize the effects of the nonresponse adjustments carried out for the final NAAL weights. For the nonresponse bias analysis, a minor adjustment was made to the NAAL and SAAL screener base weights and replicate weights for sample persons whose eligibility status was unknown (e.g., those who were unavailable after multiple attempts during the field period), in order to represent the eligible population only. Next, the weights were poststratified to one number for each sample (six SAAL states and all other states combined), and then compositing factors from the NAAL household study weighting process were applied to the screener weights to combine the state samples. The resulting composited screener weights were used in the nonresponse bias analysis at the screener level. The background questionnaire base weights for the nonresponse bias analysis were computed by applying the within-household sampling fraction to the nonresponse bias screener base weights.

#### 11.1.2 Unit Response Rates

NAAL had four stages of data collection where unit nonresponse occurred: the screener, background questionnaire, assessment, and oral module. Both unweighted and weighted response rates were computed for each stage. Screener composited base weights (discussed in section 11.1.1) were used in the screener response rate calculations, and background questionnaire composited base weights were used for the background questionnaire, assessment, and oral module calculations.

Response rates were calculated as follows:

$$RR = \frac{\sum_{i \in SR} W_i}{\sum_{i \in SR \cup SNR} W_i},$$

where

 $W_i$  = the weight of unit i;

SR = the set of participating units; and

SNR = the set of eligible nonparticipating units.

Table 11-1 contains response rates for each stage and for the survey overall. The weighted response rates are 82 percent, 76 percent, 97 percent, and 95 percent for the screener, background questionnaire, assessment, and oral module, respectively. The overall weighted response rate—the product of the screener, background questionnaire, and assessment response rates—is 60 percent. Table 11-1 also shows response rates by selected analysis variable domains (defined later in table 11-14). As the table shows, there are differential response rates among subgroups. For instance, the weighted overall survey response rate in the Northeast is 55 percent, compared with 60 to 62 percent in the other census regions.

#### 11.1.3 Item Nonresponse

Item response rates were computed for all 361 items in the background questionnaire. There were numerous reasons for item nonresponse: The respondent did not know the answer to the item or did not wish to respond, or the interview was terminated before completion and items in the latter part of the questionnaire were not asked. The numerator of the response rate consists of all item respondents; the denominator contains all unit respondents, excluding those for whom the item was skipped by the computer-assisted personal interviewing (CAPI) instrument because it was not applicable. This approach is consistent with NCES standard 1-3-5 (U.S. Department of Education, National Center for Education Statistics 2002); that is, item response rates were computed among persons who were asked the question. Westat computed both unweighted item response rates and response rates weighted with background questionnaire composited base weights.

NOTE: The following are segment-level variables derived from block group data from Census 2000: average household size, percent with less than high school education, percent speaking Spanish but not English, percent below 150% of poverty, median income, and percent who rent. The following are person-level variables captured during the screening: age, gender, race/ethnicity.

SOURCE: U.S. Department of Education, Institute of Education Sciences, National Center for Education Statistics, 2003 National Assessment of Adult Literacy.

In the background questionnaire, the interviewer asked income items in several formats, first asking for income in 1 of 13 categories and then, if the sample person refused, asking a series of questions involving broader income classifications, with the goal of placing the sample person in one of eight income categories. For the computation of response rates, the eight personal income items were combined into one personal income variable, and the eight household income items were combined into one household income variable. A sample person is considered a respondent to the income item if he or she can be put into one of the eight income categories on the basis of the series of questions. The overall personal income weighted response rate is 92.7 percent, and the overall household income weighted response rate is 88.3 percent. Across all background questionnaire items, weighted item response rates range from 87.9 percent to 100 percent, with a median of 99.9 percent.

<sup>&</sup>lt;sup>1</sup> Overall response rate is the product of the screener, background questionnaire, and assessment response rates.

<sup>&</sup>lt;sup>2</sup> Metropolitan Statistical Area.

<sup>&</sup>lt;sup>3</sup> Includes non-Hispanic White, Asian, American Indian or Alaska Native, Native Hawaiian or other Pacific Islander, and multiple races.

#### 11.1.4 Nonresponse Bias Analysis

The analysis in this section is in accordance with NCES Standard 4-4. Standard 4-4-1 states that "any survey stage of data collection with a unit or item response rate less than 85 percent must be evaluated for the potential magnitude of nonresponse bias before the data or any analysis using the data may be released." As described in section 11.1.3, all items had a response rate of more than 85 percent, so an item nonresponse bias analysis was not carried out. Two data collection stages had weighted unit response rates below 85 percent: the Screener at 82 percent and the background questionnaire at 76 percent (see section 11.1.2). Section 11.1.4.1 presents the nonresponse bias analysis for the screener, and section 11.1.4.2 provides the nonresponse bias analysis for the background questionnaire.

#### 11.1.4.1 Evaluating Bias Owing to Screener Nonresponse

A comparison of screener respondents and nonrespondents using variables known for both groups provides some indication of the potential for nonresponse bias in resulting survey estimates. The variables selected for the screener nonresponse bias analysis are displayed in table 11-2 and come from two sources: Census 2000 Public Law (PL) 94 county-level data and Census 2000 Summary File 3A (SF3A) block group-level data. The continuous variables from the SF3A were recoded into categories of approximately equal sample size.

Section 11.1.4.1.1 describes chi-square tests that may detect a significant relationship between response indicator and the analysis variable of interest. It also includes calculations of bias used in estimating the distribution of analysis variables. Section 11.1.4.1.2 provides a multivariate analysis of the relationship between response indicator and analysis variables that may reveal the areas with the greatest potential for bias before weighting adjustments. Finally, section 11.1.4.1.3 shows the effect of the weighting adjustments on the potential for nonresponse bias.

#### 11.1.4.1.1 Screener Bivariate Analysis

The distribution of screener respondents was compared with the distribution of all eligible sampled dwelling units for each of the table 11-2 variables. Weighted percentages and standard errors (SEs) were calculated in the WesVar software, using replicated composite screener base weights. To test the significance of the relationship between response status and each of the table 11-2 variables, a Rao-Scott chi-square (RS3) test of independence (Rao and Scott 1984) was performed. In addition, an estimate of bias was calculated for each domain. Bias was estimated as

$$Bias(\overline{y}_R) = (1 - W_R)(\overline{Y}_R - \overline{Y}_N), \tag{3}$$

where  $W_R$  is the weighted unit screener response rate (82.2 percent),  $\overline{Y}_R$  is the weighted estimate of the domain percentage for respondents, and  $\overline{Y}_N$  is the weighted estimate of the domain percentage for nonrespondents. A t test was performed to determine whether the bias was significantly different from 0. In accordance with NCES Guideline 5-1-4A, the t tests used a simple Bonferroni adjustment to control the overall  $\alpha$ -level (0.05) for each domain variable. The Bonferroni adjustment is appropriate for a small number of comparisons (Miller 1981). The adjustment was computed as  $\alpha' = \alpha/g$ , where g is the number of comparisons. For example, for average household size, three t tests were conducted. The Bonferroni adjustment was  $\alpha' = 0.05/3 = 0.0166$ . Therefore, any p values of less than  $\alpha'$  in the table were considered statistically significant.

The results of the Rao-Scott chi-square analysis are presented in table 11-3. At the 5 percent  $\alpha$ -level, all analysis variables have a significant relationship to screener response status except the percentage of householders who rent their homes. The results of the t tests for bias (shown in table 11-4) are consistent with the chi-square analysis. After the Bonferroni adjustment, the bias in estimating the domain percentages is significantly different from 0 for at least one domain of each variable in table 11-2, with the exception of Metropolitan Statistical Area (MSA) status and the percentage of householders who rent their homes. This finding is supported by the evidence of differential response rates among the subgroup domains shown in table 11-1. For instance, dwelling units in segments with a median income of less than \$28,400 had a relatively high weighted screener response rate of 88.5 percent. Using only

respondents, without weighting adjustments, would result in an overestimate of this domain percentage by 1.3 (or 7.68 percent), as shown in table 11-4. For this domain, the bias is fairly minor in relation to the

<sup>&</sup>lt;sup>1</sup>A t test is used to compare the means of two domain-level estimates.

standard error; the ratio of bias to the standard error is 1.02. A bias ratio over 1.96 would provide a strong indication of potential bias, since the estimate based on respondents would differ from the estimate based on eligibles by more than 1.96 times the standard error of the estimate.

Although the relationships between response status and the table 11-2 variables are significant, the differences between the distributions of respondents and eligible dwelling units are minor. The absolute bias is less than 2 for all estimated domain percentages. In addition, many of the table 11-2 variables were used in weighting adjustments, and so differences between respondents and eligible dwelling units were reduced through the weighting process (refer to section 11.1.4.1.3). Therefore, the bivariate analysis indicates minimal potential for bias at the screener level, and thus minimal impact of screener nonresponse on literacy scores, assuming that literacy scores are highly correlated with the variables used in the weighting adjustments.

#### 11.1.4.1.2 Screener Multivariate Analysis

The bivariate analysis described in section 11.1.4.1.1 is useful in explaining each variable individually. A multivariate analysis is useful in showing relationships among a number of variables. One approach is to provide a CHAID analysis. CHAID is a classification algorithm that uses chi-square tests to divide a sample into subgroups that best explain differential response rates.

The analysis in CHAID begins by dividing the sample into two or more groups on the basis of the categories of the best predictor. Each of these groups is divided into smaller subgroups on the basis of the best available predictor at each level. The splitting process continues until either no significant predictor remains or the minimum cell size requirement is met. The CHAID software displays the final subgroups in the form of a tree diagram whose branches (nodes) correspond to the groups. The resulting classification tree reveals the domains, as defined by combinations of variables, with the most differential response rates, thereby leading to domains with the highest potential for nonresponse bias.

CHAID was run with screener response status as the dependent variable and the table 11-2 variables as the independent variables. Cell sizes were limited to 300 or more dwelling units (approximately 1 percent of the sample), and up to three-way interactions were allowed (three tree levels). The resulting tree is shown in figure 11-1 and summarized in table 11-5. Twenty-five cells were formed,

with weighted response rates ranging from 59.7 percent to 93.1 percent. The lowest response rate was for the group within segments with high median income (greater than \$52,100), small average household size (2.42 or less), and a large proportion of renters (greater than 59 percent). The highest response rate was for the group within segments with low median income (\$28,400 or less) and large average household size (greater than 2.8), in the Midwest, South, or West. Median income was the dominant variable in distinguishing response rate groups, which is consistent with the results of the bivariate analysis. Region, household size, percentage of householders who rent, percentage below 150 percent of poverty, and percentage speaking Spanish but not English were also significant contributors to the CHAID tree.

Although the CHAID tree is useful for dissecting the sample into fine groups of dwelling units with response patterns as different as possible, it should be used with caution because CHAID does not take into account the complex design of the sample. Consequently, the significance level of the test may be lower than the  $0.05~\alpha$ -level indicated. If the appropriate significance level could be used, then the tree might have fewer significant response cells. Thus, the tree shown in figure 11-1 is a conservative picture because any indication of nonresponse bias shown by the CHAID results may be overstated.

Logistic regression models are also useful in identifying significant effects on response propensity. Screener response status was used as the binary dependent variable, and the table 11-2 variables were used as the predictors. The main effects model had the form

$$\log \left[ \frac{\Pr(\text{Response})}{1 - \Pr(\text{Response})} \right] = A + \sum B_i X_{ij} ,$$

where the  $X_{ij}$ 's are indicator variables for the table 11-2 variables. An F test was performed on each table 11-2 variable to determine whether it was significantly related to response propensity.

The results of the logistic regression analysis are presented in table 11-6. Three variables—region, average household size, and median income—were significantly related to response propensity at the 5 percent α-level. Response propensity is significantly lower in the Northeast than in the West, in segments with small average household sizes compared to those with large average household sizes, and in high median income segments compared to lower median income segments. The results are consistent with the CHAID analysis: The same three variables were selected into the first two levels of the CHAID tree. All three variables were used in adjusting the screener weights for nonresponse for at least one SAAL state or for the NAAL sample. Thus, the potential for nonresponse bias suggested by the multivariate analysis was reduced through the weighting adjustments, as shown in section 11.1.4.1.3.

#### 11.1.4.1.3 Potential for Screener Nonresponse Bias Remaining After Weighting Procedures

As described in section 12.1.3, weighting procedures were implemented to reduce the potential for nonresponse bias by creating nonresponse adjustment classes for which the respondents' literacy-related characteristics are similar to those of nonrespondents. The extent of the reduction in nonresponse bias depends on the correlation of the weighting class variables with literacy scores.

Tables 11-7 through 11-13 show t test results for the change in the distribution of sample cases after each screener weighting stage for the national sample and each of the six participating states. The t tests were performed to determine whether the change in the estimated domain percentage is significantly different from 0. A simple Bonferroni adjustment was used to control the overall  $\alpha$ -level at 0.05 for each domain. The adjustment is computed as  $\alpha' = \alpha/g$ , where g is the number of comparisons. Therefore, any p values less than  $\alpha'$  in the tables can be considered statistically significant. Calculations of the bias ratio of estimated percentages are also included. Although the t test may indicate a statistically significant difference, the difference may not be important. Thus, it is also useful to look at the bias ratio, the ratio of the bias to the standard error of the estimate, to gauge the importance of the potential bias. That is, if the absolute value of the bias to standard error ratio is greater than 1.96, then the ratio provides a strong indication of potential bias.

The checks were performed separately for the national NAAL household sample and each of the six SAAL states to reflect the weighting process. Unlike the results in table 11-3, these comparisons use the actual survey weights, which were processed separately for each household sample. The following comparisons were made for each of the analysis domains in table 11-2:

- Comparison of distributions from screener base weights for the estimated eligible population with those for the screener respondents only, to check for differences owing to screener nonresponse, and
- Comparison of distributions from screener base weights for the estimated eligible population with those from the screener nonresponse-adjusted weights, to check for differences even after the nonresponse adjustment to the screener.

The p values resulting from the first set of comparisons indicate a significant difference between the eligible dwelling units and respondents for most of the subgroups when base weights are used. This result is comparable to those obtained for the bivariate and multivariate analyses described in sections 11.1.4.1.1 and 11.1.4.1.2, respectively. A nonresponse adjustment was necessary to reduce the bias in estimates based on data from respondents only.

The *p* values resulting from the second set of comparisons show that for most of the subgroups, there is no significant difference between the weighted distribution of eligible dwelling units and the respondents after the nonresponse adjustment. For the national NAAL sample, the one variable with a significant difference is average household size, but the bias is minor, at less than half the standard error of the estimated percentage. Therefore, the nonresponse adjustment appears to have been effective in reducing the bias owing to screener nonresponse, to the extent that table 11-2 variables are related to literacy. For the state samples, fewer variables were available for use in nonresponse adjustments because of the smaller sample sizes; therefore, the bias estimates are generally higher. However, the bias ratio remains less than 1.00 for all estimates in the tables.

# 11.1.4.2 Evaluating Bias Owing to Background Questionnaire Nonresponse

The nonresponse bias potentially resulting from background questionnaire nonresponse was evaluated in the same manner as the analysis of screener nonresponse. Additional variables were available for the analysis. Variables known for both background questionnaire respondents and nonrespondents are shown in table 11-14 and come from three sources: Census 2000 PL-94 county-level data, Census 2000 SF3A block group-level data, and the screener. The SF3A variables were categorized the same as in the screener analysis, with approximately equal sample size in each category.

The bivariate analysis, multivariate analysis, and weighting adjustment effects are presented in sections 11.1.4.2.1 through 11.1.4.2.3, respectively.

## 11.1.4.2.1 Background Questionnaire Bivariate Analysis

The distribution of background questionnaire respondents was compared with the distribution of all eligible sample persons for each of the table 11-14 variables. Weighted percentages and standard errors were calculated using replicated composite background questionnaire base weights to reflect the complex sample design. To test the significance of the relationship between response status and each of the table 11-14 variables, a Rao-Scott chi-square (RS3) test of independence was performed. In addition, an estimate of bias was calculated for each domain. Bias was estimated as  $Bias(\overline{y}_R) = (1 - W_R)(\overline{Y}_R - \overline{Y}_N)$ , where  $W_R$  is the weighted unit background questionnaire response rate (75.6 percent),  $\overline{Y}_R$  is the weighted estimate of the domain percentage for respondents, and  $\overline{Y}_N$  is the weighted estimate of the domain percentage for nonrespondents. A t test was performed, using a simple Bonferroni adjustment, to determine whether the bias was significantly different from 0.

Table 11-14. Household Study variables used in background questionnaire nonresponse bias analysis, by source and values: 2003

Variable description	Source <sup>1</sup>	Values

<sup>&</sup>lt;sup>3</sup> Includes non-Hispanic White, Asian, American Indian or Alaska Native, Native Hawaiian or other Pacific Islander, and

The results of the chi-square analysis are presented in table 11-15. At the 5 percent  $\alpha$ -level, all analysis variables have a significant relationship to background questionnaire response status except average household size and the percentage of sample persons aged 5 to 64 who speak Spanish at home but English not well or not at all. The results of the t tests for bias (shown in table 11-16) are consistent with the chi-square analysis. For the same set of variables, the bias in estimating the domain percentages is significantly different from 0 for at least one domain. There is evidence of differential response rates among subgroups (table 11-1), contributing to the differential distributions of respondents and nonrespondents. For instance, sample persons aged 16 to 29 had a relatively high weighted background questionnaire response rate of 80.5 percent. Using only respondents, without weighting adjustments, would result in an overestimate of this domain percentage by 1.6 (or 6.59 percent), as shown in table 11-16. For this domain, the estimated bias is large in relation to the sampling error; the ratio of bias to the standard error is 3.86. Gender also shows a large bias ratio, with estimates of bias more than twice the standard error of the estimated percentages.

Although the relationships between response status and the table 11-14 variables are significant, the differences between the distributions of respondents and eligible sample persons are minor. The absolute bias is less than 2 for all estimated domain percentages. In addition, many of the table 11-14 variables were used in weighting adjustments (including gender and age, which showed indications of bias), and so differences between respondents and eligible sample persons were reduced through the weighting process (refer to section 11.1.4.2.3). Therefore, the bivariate analysis indicates minimal potential for bias at the background questionnaire level, and thus minimal impact of background questionnaire nonresponse on literacy scores, assuming that literacy scores are highly correlated with the variables used in the weighting adjustments.

#### 11.1.4.2.2 Background Questionnaire Multivariate Analysis

The CHAID software was used in the background questionnaire multivariate analysis to explain differential response rates. For more information on CHAID, refer to section 11.1.4.1.2.

CHAID was run with background questionnaire response status as the dependent variable and the table 11-14 variables as the independent variables. Cell sizes were limited to 230 or more sample persons (approximately 1 percent of the sample), and up to three-way interactions were allowed (three tree levels). The resulting tree is shown in figure 11-2 and summarized in table 11-17. Fifteen cells were formed, with weighted response rates ranging from 67.4 percent to 86.9 percent. The lowest response rate was for males aged 30+ in segments with high median income (greater than \$52,100). The highest response rate was for persons aged 16 to 29 in segments with moderately low median income (\$28,401 to \$37,850) and large average household size (greater than 2.8). Median income was the dominant variable in distinguishing response rate groups, which is consistent with the results of the bivariate analysis. Gender, age, region, household size, and race/ethnicity were also significant contributors to the CHAID tree.

A logistic regression main-effect model was used to identify significant effects on background questionnaire response propensity. Only main effects were included because of limited degrees of freedom and because interactions were identified in the previous CHAID analysis. Background questionnaire response status was used as the binary dependent variable, and the table 11-14 variables were used as the predictors. The results of the logistic regression analysis are presented in table 11-18. Five variables—region, median income, age, gender, and race/ethnicity—were found to be significantly related to response propensity at the 5 percent  $\alpha$ -level. The regression coefficient estimates for these five variables are provided in table 11-18 to show the direction of the relationship with response propensity. For instance, the table shows that males are significantly less likely to respond than females. The results are consistent with the CHAID analysis: The five variables were included in the first three levels of the CHAID tree. All variables found to be significantly related to response propensity in the multivariate analysis, including household size from CHAID, were used in the background questionnaire weighting adjustments. Thus, the potential for nonresponse bias suggested by the multivariate analysis should be reduced through the weighting adjustments, as described in the next section.

\_

<sup>&</sup>lt;sup>2</sup>A more detailed dwelling unit-level household count was used for the background questionnaire weighting adjustments in place of the segment-level variable for average household size included here.

# 11.1.4.2.3 Potential for Background Questionnaire Nonresponse Bias Remaining After Weighting Procedures

As described in section 12.1.4, the weighting procedures for the main NAAL background questionnaire were implemented to reduce the potential for nonresponse bias by creating nonresponse adjustment classes for which respondents' literacy-related characteristics are similar to those of nonrespondents. Other background questionnaire weighting steps were conducted to calibrate the weights to known totals from the 2003 Current Population Survey and then combine the NAAL and SAAL samples through composite weighting. Steps performed after the nonresponse adjustment are expected to have little impact on nonresponse bias and thus are not included in this analysis.

Tables 11-19 to 11-25 show and test the change in the distribution of the sample cases before and after the background questionnaire nonresponse adjustment for the national household sample and each of the six participating states. T tests were performed using a Bonferroni adjustment to test whether the difference in estimated percentages is significantly different from 0. To help determine whether statistically significant results are also meaningful, calculations of bias ratios are also included. The checks were performed separately for the national NAAL household sample and for each of the six SAAL states, to reflect the weighting process. Unlike the results in table 11-15, these comparisons use the actual survey weights, which were processed separately for each sample and include screener nonresponse adjustments. The following comparisons were made for each of the analysis variables in table 11-14:

- Comparison of distributions from background questionnaire base weights with those for background questionnaire respondents only, to check for differences owing to background questionnaire nonresponse, and
- Comparison of distributions from background questionnaire base weights with those from the background questionnaire nonresponse-adjusted weights, to check for differences remaining after nonresponse adjustment to the background questionnaire.

The *p* values resulting from the first set of comparisons indicate a significant difference between the eligible sample persons and respondents for most of the subgroups when background questionnaire base weights are used. A nonresponse adjustment was necessary to reduce the bias in estimates based on respondents only.

As shown in table 11-19, significant differences between eligible NAAL sample persons and respondents remain for some categories of region, MSA status, and median income after the nonresponse adjustment. However, the absolute bias in the percentage distribution of the majority of table 11-14 variables decreased and is less than 2 percentage points for all domains. In addition, the bias is less than

twice the standard error of the estimated percentage for all statistically significant differences, so the differences appear to be minor. Tables 11-20 to 11-25 show similar results for the six SAAL states. Although the bias remains significantly different from 0 for some domains, after the nonresponse adjustment it is never more than twice the standard error of the estimated percentages. Therefore, the nonresponse adjustment appears to have been effective in reducing the bias owing to background questionnaire nonresponse, to the extent that table 11-14 variables are related to literacy.

#### 11.1.5 Conclusion

The household sample was subject to unit nonresponse from the screener, background questionnaire, assessment, and oral module and to item nonresponse to background questionnaire items. While all background questionnaire items had response rates of more than 85 percent, two stages of data collection—the screener and the background questionnaire—had unit response rates below 85 percent and thus required an analysis of the potential for nonresponse bias.

In bivariate unit-level analyses at the screener and background questionnaire stages, estimated percentages for respondents were compared with those for the total eligible sample to identify any potential bias owing to nonresponse. Although some statistically significant differences exist, the potential for bias is small because the absolute difference between estimated percentages is less than 2 percent for all domains considered. Multivariate analyses were conducted to further explore the potential for nonresponse bias by identifying the domains with the most differential response rates. These analyses revealed that the lowest response rates for the screener were among dwelling units in segments with high median income, small average household size, and a large proportion of renters. The lowest response rates for the background questionnaire were among males aged 30 or older in segments with high median income. However, the variables used to define these areas and other pockets with low response rates were used in weighting adjustments. The analysis showed that weighting adjustments were highly effective in reducing the bias. The general conclusion is that the potential amount of nonresponse bias attributable to unit nonresponse at the screener and background questionnaire stages is likely to be negligible.

#### 11.2 PRISON LITERACY STUDY

As in the household study, the NAAL prison study estimates are subject to potential bias owing to nonresponse at various stages of data collection. Data were collected using a background questionnaire, an assessment, and an oral module, which included multiple components. This section provides a systematic analysis of bias arising from nonparticipating prisons, nonresponding inmates, and item nonresponse. Section 11.2.1 provides unweighted and weighted response rates at the unit level. Section 11.2.2 summarizes the response rates at the item level. Section 11.2.3 provides the nonresponse bias analysis for the prison study.

#### 11.2.1 Unit Nonresponse

The Prison Study had four stages of data collection where unit nonresponse occurred: (1) prison participation, (2) inmate background questionnaire, (3) inmate assessment, and (4) inmate oral module.

Variables known for both respondents and nonrespondents were used as selected analysis domain variables. The variables came from the following sources:

- Prison-level data from the 2000 Census of State and Federal Adult Correctional Facilities (referred to as the Census in this report);
- Prison-level data from the 2003 American Correctional Association (ACA) Directory;
- Prison-level updates obtained from websites and through telephone calls; and
- Inmate data from the background questionnaire.

Prison-level base weights were used in the weighted prison-level response rate calculations, and background questionnaire base weights were used for the background questionnaire, assessment, and oral module calculations. Response rates were calculated in the same manner as presented in the formula in section 7.1.1. The overall assessment weighted response rate is the product of the weighted response rates from the prison-level, background questionnaire and assessment.

Table 11-26 displays the variables and their sources. Table 11-27 shows the weighted unit response rates (refer to tables 7-13 and 7-14 for unweighted response rates for the prison study). There was a 97.5 percent weighted response rate at the prison level. Among types of prisons, state prisons had the lowest response rate (97.1 percent). Among security levels, prisons with supermaximum and maximum security levels combined had the lowest response rate (96.6 percent). Looking at gender

composition, the only nonparticipating prisons were male-only facilities, with a response rate of 97.3 percent. Among census regions, the Midwest was the only region that experienced nonresponse, with a response rate of 87.9 percent.

<sup>—</sup>Not available.

<sup>1</sup> The overall response rate is the product of the response rates from the prison level, background questionnaire, and assessment.

<sup>2</sup> Includes non-Hispanic White, Asian, American Indian or Alaska Native, Native Hawaiian or other Pacific Islander, and

At the background questionnaire level, the weighted response rate was 90.6 percent. Across the domains, the West region had the lowest response rate (82.8 percent). For background questionnaire respondents, the weighted response rate was 98.8 percent for the assessment and 96.9 percent for the oral module. Response rates for the assessment and oral module were all above 94 percent, with the exception of relatively low oral module response rates in the Northeast (90.9 percent) and for Hispanic adults (93.8 percent) and relatively low assessment and oral module response rates (90.9 percent) for administrative prisons.

The overall weighted response rate for the prison study was 87.2 percent. The lowest response rate among types of prisons was for state prisons (86.4 percent). Among security levels, prisons classified as either supermaximum or maximum had the lowest response rate (80.4 percent). Looking at gender composition, male-only prisons had the lowest response rate (86.8 percent). Among census regions, the Midwest and West regions had the lowest response rates (81.2 percent and 81.4 percent, respectively).

## 11.2.2 Item Nonresponse Rates

Response rates were calculated for 280 items on the prison study background questionnaire. Two hundred items had a 100 percent response rate, 78 items had a response rate between 99.0 and 99.9 percent, 1 item had an 80.5 percent response rate, and 1 item had a 71.0 percent response rate. The last two items are shown in table 11-28.

Table 11-28. Prison Study item response rates below 85 percent, by variable: 2003

Variable	Description	Number of eligibles	Unweighted item response rate (percent)	Weighted item response rate (percent)
BQ1830	What was the highest level of education your mother (stepmother, or female guardian) completed?	1,161	80.3	80.5
BQ1840	What was the highest level of education your father (stepfather, or male guardian) completed?	1,161	70.7	71.0

SOURCE: U.S. Department of Education, Institute of Education Sciences, National Center for Education Statistics, 2003 National Assessment of Adult Literacy.

The numerator in the item response rate consisted of the item respondents; the denominator contained all unit respondents, excluding those with a valid skip for the item. Unweighted item response rates ranged from 70.7 percent to 100 percent, with a median of 100 percent. Weighted item response rates ranged from 71.0 percent to 100 percent, with a median of 100 percent.

#### 11.2.3 Nonresponse Bias Analysis

As noted in section 11.1.4, NCES Standard 4-4-1 requires an evaluation of the potential magnitude of nonresponse bias for any survey stage with a unit or item response rate of less than 85 percent. The final prison and inmate (for the background questionnaire, assessment, and oral module) weighted response rates were all above 85 percent. Because of the high response rate, the nonresponse bias analysis was not necessary to examine unit nonresponse.

For item nonresponse, only two items on the background questionnaire fell below the 85 percent weighted response rate threshold. These two items are "What was the highest level of education your mother (stepmother, or female guardian) completed?" with an 80.5 percent weighted response rate, and "What was the highest level of education your father (stepfather, or male guardian) completed?" with a 71.0 percent weighted response rate. Because these two items do not meet the NCES nonresponse standard, a bivariate analysis (section 11.2.3.1), an item nonresponse bias estimation (section 11.2.3.2), and a multivariate analysis (section 11.2.3.3) were performed for each item to examine the potential bias owing to nonresponse.

#### 11.2.3.1 Bivariate Analysis

For the two items with a low response rate in table 11-28, the distributions of item respondents and eligibles (i.e., unit respondents) were compared on survey domains such as key characteristics and background questionnaire items with response rates of 100 percent. To test for independence between the response indicators and survey domains, a Rao-Scott (RS3) chi-square test was computed, using WesVar. Final weights were used in the analysis. The results are shown in table 11-29. Replicate weights were used to adequately reflect the effect of two-stage cluster sampling.

NOTE: Details may not sum to totals because of rounding.

SOURCE: U.S. Department of Education, Institute of Education Sciences, National Center for Education Statistics, 2003 National Assessment of Adult Literacy.

The chi-square tests show that there was a significant relationship between the response indicator for "What was the highest level of education your mother (stepmother, or female guardian) completed?" and 5 of the 20 survey domains (gender, race/ethnicity, education, ever used or not used a computer, and health).

The chi-square tests also show a significant relationship between the response indicator for "What was the highest level of education your father (stepfather, or male guardian) completed?" and 4 of the 20 survey domains (race/ethnicity, education, ever used or not used a computer, and ever received food stamps).

## 11.2.3.2 Item Nonresponse Bias Estimates

To understand the magnitude of the potential bias, estimates of bias were computed (as shown in table 11-30). T tests were performed to determine whether the bias was significantly different from 0. The t tests used a simple Bonferroni adjustment so that the overall  $\alpha$ -level equaled 0.05 for each domain variable. The adjustment was computed as  $\alpha' = \alpha/g$ , where g is the number of comparisons. For example, for prison security level, three t tests were conducted. The Bonferroni adjustment is  $\alpha' = 0.05/3 = 0.0166$ . The results are fairly consistent with the chi-square analysis described in section 11.2.3.1.

With regard to mother's education, the survey domains with statistically significant bias estimates are the Midwest, males, females, Hispanics, levels of education, and having fair health. With regard to father's education, the survey domains with statistically significant bias estimates are the Midwest, race/ethnicity other than Black or Hispanic, levels of education, and ever used or not used a computer.

Even though there are some statistically significant relationships between the response indicators and the survey domains, there do not seem to be important indications of potential bias. Almost all absolute bias estimates are within 2 percentage points. However, among the statistically significant bias estimates, there are exceptions for mother's education, namely, –2.1 percent (–11.73 percent relative bias) for Hispanic inmates, –4.3 percent for inmates with low educational attainment (–11.47 percent relative bias), and 4.3 percent for inmates with high educational attainment (6.88 percent relative bias).

NOTE: Details may not sum to totals because of rounding.

For father's education, there are also exceptions among the statistically significant bias estimates, namely, 3.5 percent absolute bias for race/ethnicity other than Black or Hispanic (9.64 percent relative bias), -2.9 percent for inmates with low educational attainment (-7.73 percent relative bias), and 2.9 percent for inmates with high educational attainment (4.64 percent relative bias), as well as for inmates who either use (2.1 percent, 8.40 percent relative bias) or do not ever use (-2.1 percent, -2.8 percent relative bias) a computer.

## 11.2.3.3 Multivariate Analysis

The bivariate analysis described in section 11.2.3.2 is useful for explaining each domain variable individually. A multivariate analysis is useful in showing relationships among a number of domain variables for the item (BO1830, BO1840) response indicator.

For the multivariate analysis of item nonresponse, CHAID was used to divide the sample into subgroups that best explain differential response rates. The resulting classification trees reveal the survey domains, as defined by combinations of variables with the most differential response rates, thereby leading to survey domains with the highest potential for nonresponse bias. Item response status was used as the dependent variable, and the survey domains indicated in table 11-29 were the predictors.

The trees for the low response rate items are displayed in figures 11-3 and 11-4. For mother's education, the variables used to form the CHAID cells were education, region, "In general, how would you rate your overall health?" and race/ethnicity indicators (figure 11-3). Inmates with low levels of education in the Northeast, South, and West show the greatest potential for nonresponse bias for this item because those inmates have the lowest response rate (69.5 percent). Inmates who had high levels of education, considered themselves to be in excellent or very good health, and were non-Hispanic had the lowest potential for nonresponse bias for this item, with the highest response rate (91.0 percent).

For father's education, the variables race/ethnicity, "Have you ever received food stamps?" "How well do you understand English when it is spoken to you?" "In general, how would you rate your overall health?" "How well do you write English?" and marital status were used to form the response cells (figure 11-4). The last three variables were not significant when considered individually (as shown in table 11-29). However, through interactions with other explanatory variables, they become important

variables. Inmates who are of other than Black or Hispanic race/ethnicity, are in fair or poor health, and have received food stamps showed the greatest potential for nonresponse bias for this item, with the lowest response rate (48.6 percent). In contrast, Hispanic and non-Hispanic Black inmates who understand English well and have never been married had the lowest potential for nonresponse bias for this item, with the highest response rate (82.3 percent).

#### 11.2.4 Conclusion

Through the systematic analysis described above, several prison study variables that were known for both respondents and nonrespondents were analyzed to see whether there was an important impact of nonresponse bias. At the unit level, concern over nonresponse is minimal because the response rates were acceptably high for each of the data collection stages. Out of the hundreds of background questionnaire items, only two were below NCES standards for response rates.

For the background questionnaire item asking for mother's education, the CHAID analysis shows that the domain with the lowest response rate (69.5 percent) includes inmates with less than a high school education who live in the Northeast, South, or West. Other important domains that may affect the potential for bias, as given in the bias estimates, are Hispanic race/ethnicity and inmate education level. Some other domains showed some significant relationship with the response indicator for mother's education but did not show important levels of bias based on the bias ratio.

For the background questionnaire item asking for father's education, the CHAID analysis shows that the domain with the lowest response rate (48.6 percent) was inmates of non-Black, non-Hispanic race/ethnicity who rated their health as fair or poor and who had received food stamps. Other important domains that may affect the potential for bias as given in the bias estimates are race/ethnicity other than Black or Hispanic, inmate education levels, and levels of computer use. Some domains given in the CHAID tree include not being able to understand English well or not at all, not being able to write English well, and having a marital status other than never married; however, the impact of these CHAID domains is dependent on other variables, as shown in figure 11-4. Some other domains showed some significant relationship with the response indicator for father's education but did not show important levels of bias based on the bias ratio.

The results of the prison study nonresponse bias analysis show very little potential for nonresponse bias. In fact, there is minimal concern for unit-level bias, and there is concern for only two background questionnaire items. Some caution should be used when analyzing parent's education with the variables that showed importance in the CHAID analysis and in the bivariate analysis.
